## ABSTRACT

Competitive, spatial price equilibrium models have been used extensively by international agricultural trade economists as research and policy analysis tools. These mathematical models of international trade are solved on large mainframe computers. It has become feasible to solve small spatial price equilibrium models with microcomputers. This report describes a microcomputer program designed to solve small, single commodity spatial equilibrium models. The program, GTP (Generalized Transportation Problem), was developed on an IBM PC-XT personal computer, but it should run on most microcomputers based on the 8086 and 8088 microprocessors.

Keywords: Trade, spatial equilibrium, algorithm, computer program.

## ACKNOWLEDGMENTS

Charles Hallahan, Jerry Sharples, Praveen Dixit, and John Wainio for review.

## SUMMARY

This report describes a computer program designed to solve small, single commodity, competitive, spatial price equilibrium models on an IBM personal computer. The computer program, GTP (Generalized Transportation Problem), allows up to 10 exporting regions and 25 importing regions. The user may specify lower and upper bound constraints on export and import quantities and on individual trade flows between exporting and importing regions. Specific and ad valorem tariffs and exchange rates are also allowed. Transportation costs between exporting and importing regions must be fixed per unit costs. Program GTP enforces a fixed functional form for excess supply and demand schedules. This functional form permits scalar, linear, constant elasticity, and a mixed type schedule for the excess functions.

Data for a particular spatial equilibrium problem is entered to the program interactively, and in the case of a previously defined problem, may be loaded into the program from a data file. Once an input data file is read into the program, the problem defined by the data file may be modified and resolved. Multiple versions of the input data for the same basic problem may be generated and saved on disk files. The program allows the user to write simple reports to the computer screen or to write more detailed reports to a file which may be routed to a printer.

A world wheat trade model containing 6 exporting regions and 16 importing regions is setup and solved to illustrate the use of GTP.

# GTP: A Microcomputer Program for the Spatial Equilibrium Problem

Forrest D. Holland

## INTRODUCTION

The report contains five parts. The first section presents the competitive, spatial price equilibrium model in terms of equilibrium conditions and constraints, lists the assumptions of the model, and presents the spatial equilibrium model in mathematical terms. The second section gives a brief history of the solution algorithm and a short, simplified description of the solution procedure. The third section focuses on the GTP (Generalized Transportation Problem) program commands, command functions, command syntax, and input and output data files. The fourth section deals with computer hardware requirements, specifically minimum memory and the desirability of an 8087 mathematical coprocessor. The final section presents a detailed example using an actual model of international wheat trade. This section presents the step-by-step process used to input model data, solve a model, and generate hardcopy reports with program GTP.

## THE SPATIAL PRICE EQUILIBRIUM MODEL

The competitive, spatial price equilibrium model is used to describe the pricing and allocation of a commodity between exporting and importing regions separated by transportation costs. The assumptions of this model are (a) the markets behave competitively, (b) each region represents a distinct market place, (c) the commodity traded is homogeneous, (d) the quantities supplied and demanded are well-behaved functions of price, (e) the transportation costs are constant per unit costs, and (f) the exporting and importing regions may be specified a priori.

Spatial equilibrium models are usually static models. The competitive spatial price equilibrium model provides solution values given alternative policies or shocks, but does not provide information pertaining to the adjustment process embodied in the transition from one solution to another. An analyst typically builds a base period model, then asks "what if" type questions by varying model parameters and re-solving for the equilibrium.

### Mathematical Model

The competitive, spatial price equilibrium problem may be expressed mathematically as a surplus maximization problem or equivalently as a set of

equilibrium conditions. I chose to state the problem in terms of equilibrium conditions.

Find:  $P_i$ ,  $P_j$ ,  $S_i$ ,  $D_j$ , and  $X_{ij}$

Such that:  $S_i = S_i(P_i) = X_{i1} + X_{i2} + \dots + X_{im}$

$D_j = D_j(P_j) = X_{1j} + X_{2j} + \dots + X_{nj}$

$S_1 + S_2 + \dots + S_n = D_1 + D_2 + \dots + D_m$

Subject to:  $SL_i \leq S_i \leq SU_i$

$DL_j \leq D_j \leq DU_j$

$XL_{ij} \leq X_{ij} \leq XU_{ij}$

$P_i > 0$

$P_j = \text{Minimum}_{(i)} [ L_j(P_i: XL_{ij} < X_{ij} < XU_{ij} ) ]$

Where:  $i = 1, n$  indexes exporters (sources),

$j = 1, m$  indexes importers (sinks),

$P_i$  = price of the  $i^{\text{th}}$  exporter,

$P_j$  = price of the  $j^{\text{th}}$  importer,

$S_i$  = excess supply of the  $i^{\text{th}}$  exporter,

$D_j$  = excess demand of the  $j^{\text{th}}$  importer,

$S_i(P_i)$  = excess supply schedule of the  $i^{\text{th}}$  exporter,

$D_j(P_j)$  = excess demand schedule of the  $j^{\text{th}}$  importer,

$X_{ij}$  = trade flow from the  $i^{\text{th}}$  exporter to the  $j^{\text{th}}$  importer,

$SL_i$  = lower bound constraint on the  $i^{\text{th}}$  exporter,

$SU_i$  = upper bound constraint on the  $i^{\text{th}}$  exporter,

$DL_j$  = lower bound constraint on the  $j^{\text{th}}$  importer,

$DU_j$  = upper bound constraint on the  $j^{\text{th}}$  importer,

$XL_{ij}$  = lower bound constraint on the  $ij^{\text{th}}$  trade flow,

$XU_{ij}$  = upper bound constraint on the  $ij^{\text{th}}$  trade flow, and

$L_j(P_i)$  = a price linkage function relating importer prices to exporter prices through exchange rates, tariffs, and transportation costs.

### Price Linkage Mechanism

The price relationship between exporters (sources) and importers (sinks) is expressed through a price linkage function. The price linkage function describes the "wedge" between exporter and importer prices. In its simplest form, the price linkage function states that if an exporter and an importer are trade partners and no binding trade flow constraint exists between them, then their prices must differ by exactly the cost of transportation. In the more general form, the price linkage function contains exchange rates, specific and ad valorem tariffs, and transportation costs. The price linkage between the  $i^{\text{th}}$  exporter and the  $j^{\text{th}}$  importer may be expressed:

$$L_j(P_i) = (((P_i * (V_i + 1) + U_i) * E_i + T_{ij}) * (V_j + 1) / E_j) + U_j$$

Where  $V_i$  = an ad valorem tariff imposed by the  $i^{\text{th}}$  exporter,

$U_i$  = a specific tariff (in domestic currency units) imposed by the  $i^{\text{th}}$  exporter,

$E_i$  = exchange rate (base relative to domestic currency) for the  $i^{\text{th}}$  exporter,

$T_{ij}$  = transportation cost (in base currency units) from the  $i^{\text{th}}$  exporter to the  $j^{\text{th}}$  importer,

$V_j$  = an ad valorem tariff imposed by the  $j^{\text{th}}$  importer,

$U_j$  = a specific tariff (in domestic currency units) imposed by the  $j^{\text{th}}$  importer, and

$E_j$  = exchange rate (base relative to domestic currency) for the  $j^{\text{th}}$  importer.

The solution algorithm in GTP links import prices to export prices by choosing the least cost supplier for each importing region. If a trade flow constraint is binding, then the next lowest priced exporter supplies the remainder of the import demand. Notice that the price linkage function is analogous to the first order conditions for the surplus maximization formulation of the problem.

### Excess Schedules

The excess supply and demand schedules may be simple schedules which map from a commodity price to quantity supplied or demanded, or they may be composite schedules which contain beginning inventory, a production schedule, primary and secondary domestic use schedules, and an ending inventory schedule. The solution algorithm used in program GTP is capable of finding solutions to spatial price equilibrium problems with very complicated excess schedules which may be nonsmooth (the derivative of the excess schedule with respect to price is discontinuous) and may even be correspondences (the mapping from price to quantity is point to set rather than point to point).

In program GTP the excess supply and demand functions are restricted to a particular functional form. Restricted functional forms are used in the program to simplify use of the solution package and to simplify the computer program. The excess schedules are of the form:

$$\text{Quantity} = \text{Alpha} + \text{Beta} * (\text{Price})^\text{Gamma}$$

This functional form allows scalar (Beta=0 and/or Gamma=0, linear (Beta≠0, Gamma=1), constant elasticity (Alpha=0, Beta>0, Gamma≠0), and mixed schedules (Alpha≠0, Beta≠0, and Gamma≠0).

### Constraints, Tariffs, and Exchange Rates

The market constraints  $SL_i$ ,  $SU_i$ ,  $DL_j$ , and  $DU_j$  and the trade flow constraints  $XL_{ij}$  and  $XU_{ij}$  may be used to modify the competitive model to reflect "real world" conditions. The market constraints may correspond to actual quotas or may be used to represent price band policies. The trade flow constraints may reflect bilateral trade agreements, selective embargoes, or other politically induced trade barriers. The specific tariffs  $U_i$  and  $U_j$  are used to impose a per unit tax (or subsidy) on each unit of the commodity traded. Ad valorem tariffs,  $V_i$  and  $V_j$ , apply to the value of trade rather than the quantity of trade. Specific tariffs are expressed in units of domestic currency per commodity unit, and ad valorem tariffs are expressed as a percentage of the value of trade.

The exchange rate vectors,  $E_i$  and  $E_j$ , specify the relationship between the domestic currencies of markets in the model. One of the regions (markets) in the model is chosen as a base, and the currencies of the other regions are expressed in terms of the base currency through the exchange rate vectors.

### Further Reading

The competitive, spatial price equilibrium model enjoys a lengthy history. Enke [1] and Samuelson [5] presented the basic model and suggested solution algorithms in the early 1950's. <sup>1/</sup> Takayama and Judge's [6] formulation of the problem in quadratic programming terms in the midsixties allowed researchers to model and solve "real world" spatial equilibrium problems. Takayama and Judge's book [7] on modeling over space and time is an excellent presentation of spatial and related equilibrium models.

Of course the spatial equilibrium model is not without faults. The assumptions are somewhat restrictive, and empirical models are generally unable to replicate observed trade flows. In a recent survey of agricultural trade models, Thompson [8] discusses the strengths and weaknesses of spatial equilibrium models and alternative models of international trade.

### THE SOLUTION ALGORITHM

The solution algorithm employed by program GTP to find a competitive, spatial price equilibrium is called the Vector Sandwich Method (VSM). The VSM algorithm is one of a class of algorithms referred to by various authors as fixed point, equilibria, homotopy, or path-following algorithms. No particular term dominates, but all of the algorithms in the class are path-following in the sense that given an initial point they follow a path leading to an equilibrium point.

---

<sup>1/</sup> Numbers in brackets refer to references listed in the References section.

Kuhn and MacKinnon [3] originally developed the VSM algorithm to solve general equilibrium problems. The algorithm was subsequently applied to the generalized transportation problem (competitive, spatial price equilibrium) by MacKinnon [4]. I have used the VSM algorithm to solve simultaneous nonsmooth, nonlinear equation systems in market simulation models and to solve competitive, spatial price equilibrium problems.

### Solution Procedure

The VSM algorithm is a simplicial approximation algorithm. The solution space is divided into nice sets called simplices, and a sophisticated search procedure is used to generate a path leading to an equilibrium point. The algorithm moves from simplex to simplex following a set of labeling rules. On each simplex a piecewise linear approximation to the underlying equation system is formed. Since the simplices are associated with piecewise linear approximation to the underlying equilibrium, the algorithm also forms a piecewise linear approximation to the solution path as it follows a path leading from an initial solution guess to an equilibrium point.

To move from an initial point to an equilibrium point, the algorithm needs only price vectors and the quantity vectors associated with the price vectors. There is no objective function and there are no derivatives, or system of path-following differential equations to evaluate. This results in marked flexibility in excess equation formulation and makes the algorithm relatively easy to use, but it also makes the algorithm converge more slowly than algorithms which use derivative information and/or exploit the structure of a particular equilibrium problem.

The inner workings of the algorithm are much more mathematically complex than the above description implies. The VSM algorithm is a complementary pivot algorithm which involves pivoting on the simplex vertices and basis changes associated with labeling vectors and vertex weights. From an empirical viewpoint, the mathematical structure of the algorithm is not that important. What is important is that this algorithm and similar algorithms can be used to solve spatial price equilibrium problems.

Simplicial subdivision algorithms do have an interesting computational property. Given some mild assumptions concerning the division of the solution space into simplices and the relationship between the piecewise linear approximations on adjacent simplices, these algorithms cannot cycle. A finite (perhaps large) number of function evaluations is guaranteed. In other words, if your problem has an equilibrium point, this algorithm will find it. If your problem does not have an equilibrium point, my program will either give you a message indicating that the algorithm did not converge to an equilibrium or "lock-up" your computer.

### Problem Size

The VSM algorithm is not appropriate for solving large spatial equilibrium problems. The dimension of the search problem for the VSM algorithm is related to the cube of the number of endogenous prices. For the problem considered here, the number of endogenous prices is one plus the number of exporters in the spatial equilibrium model. This is the reason that I have constrained program GTP to no more than 10 exporting regions. The relationship between computational cost and the number of importing regions appears to be linear; and therefore, is rather insignificant compared with the computational cost

associated with exporting regions. I set the program maximum of 25 importing regions somewhat arbitrarily. This is a reasonable maximum number of importing regions for most spatial equilibrium models which would be solved on a microcomputer.

### Further Reading

Readers interested in simplicial subdivision algorithms and other path-following algorithms for solving economic equilibria and similar problems will find a very readable discussion of the current "state-of-the-art" in Zangwill and Garcia [9].

### USING THE COMPUTER PROGRAM

The computer program has two versions, GTP-SLOW.EXE and GTP-8087.EXE. The differences between the two versions of the program are explained in the Computer Hardware Requirements section. The program may be executed by typing GTP-SLOW or GTP-8087 if the program file is on the "logged drive," otherwise a drive specifier must precede the file name; for example, B:GTP-SLOW.

When the program begins execution, it prints a header which writes the program purpose and my name and phone number. The program then prompts for an initial input data file name (IDF) and an initial output data file name (ODF). The purpose and use of these two data files are explained in the Command Function Syntax section. After the initial data file names are entered or defaulted (by entering a carriage return; hereafter, abbreviated <return>), the program prompt appears. The program prompt is a solid right arrow which looks something like the usual DOS (Disk Operating System) prompt. The program is then ready for your input.

### Commands

The program has only five commands (table 1). Two commands, SEE and SET, require the user to specify a function (subcommand). The SEE command may be used with all 30 functions (table 2) and the SET command may be used with the first 24 functions (IDF through RPC). The commands and functions are three letter strings which may be entered in either upper or lower case or both. If you fail to enter a command or function or misspell one, the program writes a list of legal commands or functions to the screen. If you need a list of the commands, enter <return> at the program prompt, and a list will appear on the screen. A list of functions (subcommands) may be obtained by entering SEE <return> or SET <return>.

Table 1--Program Commands

Name	Definition	Name	Definition
SEE	See Current Value(s)	SET	Set New Value(s)
RUN	Run The Solver	RPT	Write Reports
END	End Program Execution		

Command names reflect their purpose. The SEE command displays the current value of the specified function on the screen. For instance, SEE NXS displays the current value for the number of exporters, while SEE TFL displays the values for all lower bound trade flow constraints. The SET command allows the user to change various parameters. SET displays the old (current) value of an item on the screen and prompts for a new (replacement) value. If no new value is input, then the old value is retained by default. The SEE and SET commands differ from the other commands in that a function (subcommand) must be specified to tell the program what is to be seen or set.

The RUN command calls an error checking routine which scans the problem data for errors and inconsistent constraints. If an error is found, program GTP flags it by writing a message to the screen and the program returns its prompt (the solid right arrow). If this occurs, the user should correct the problem and then invoke the RUN command again. The error checking routine also flags some conditions which may or may not be errors. In this case, the user is asked whether or not the problem should be passed to the solution algorithm. If the error checking routine fails to find fatal errors or potential errors, the solution algorithm is automatically invoked. The solution algorithm writes a simple report of its progress while solving the problem. This report is described in detail below, under the heading "Convergence Progress".

Hardcopy reports are indirectly generated with the RPT command. RPT prompts the user to determine which reports to generate (table 3) and writes the reports on a formatted ASCII file. The user specifies the file name for these reports with the SET ODF command-function string. The user must then route this file to the printer using the DOS PRINT command. The reports generated with the RPT command are in a 133 column format and use standard form-feed

Table 2--SEE and/or SET Functions 1/

Name	Definition	Name	Definition
IDF	Input Data File Name	ODF	Output Data File Name
NXS	Number of Exporters	NMS	Number of Importers
LXS	Exporter Names	LMS	Importer Names
QLX	Exporter Supply Lower Bounds	QLM	Importer Demand Lower Bounds
QUX	Exporter Supply Upper Bounds	QUM	Importer Demand Upper Bounds
VTX	Exporter Ad Valorem Tariffs	VTM	Importer Ad Valorem Tariffs
STX	Exporter Specific Tariffs	STM	Importer Specific Tariffs
ERX	Exporter Exchange Rates	ERM	Importer Exchange Rates
TFL	Trade Flow Lower Bounds	TFU	Trade Flow Upper Bounds
CTS	Cost of Transport Services	TLE	Run Title
QSX	Exporter Supply Schedules	QDM	Importer Demand Schedules
PGX	Exporter Initial Prices	RPC	Relative Price Convergence
PTX	Exporter Price Report	PTM	Importer Price Report
QTX	Exporter Quantity Report	QTM	Importer Quantity Report
TFX	Exporter Trade Flow Report	TFM	Importer Trade Flow Report

1/ The first 24 functions (IDF through RPC) may be used with both the SEE and SET commands. The last six functions (PTX through TFM) may be used only with the SEE command.

(ASCII 12) and line-feed (ASCII 10) control codes. If you use an 80 column printer, you will need to set your printer to condensed print mode before you route the ODF file via the DOS PRINT or COPY commands. The file produced by the RPT command is compatible with Epson and Okidata dot matrix printers.

The END command prompts for file handling information for the input data file (IDF) and output data file (ODF), then terminates the program.

### Functions

Most of the functions in table 2 are arranged in matched pairs pertaining to exporters and importers, respectively. For example, NXS is the function associated with the number of exporters, and the corresponding importer function is NMS. Exceptions to this rule include IDF and ODF, the input and output file name functions; TFL and TFU, the two trade flow bound functions; CTS, the transport cost function; TLE, the run title function; PGX, the initial export prices function; and RPC, the relative price convergence function.

The file handling functions, IDF and ODF, are used to specify input and output file names and file disposition. The computer program is designed to read and/or write input data files the user created from the data input. For example, if you create a model of international rice trade, you may save the rice model data on a file and subsequently load the data file in a later computer run. Before discussing the IDF and ODF functions in detail, I think some definitions and caveats should be considered.

There are two distinct types of files as far as this computer program is concerned: old refers to an existing file containing data and new refers to a file that does not contain data. Old files may be opened and their contents read into computer memory, while new files may be opened and have computer memory written to them. Files may be opened as either new or old files. If an old file is opened as a new file, the original contents of the file are automatically destroyed. This means that if you tell my program to use an existing data file as if it were a new file, then the contents of the original data file are irrevocably destroyed. It is difficult to accidentally destroy an existing disk file, but I make no warranty. Files also must be closed and their disposition declared. Files may be closed with keep (which saves the disk file) or delete (which destroys the disk file). I strongly suggest that

you never use an original file with my program or any other microcomputer program. Make at least two backup copies of any valuable files, and use one of the backup copies in place of the original file.

I named the input data file function IDF. Data from a specific spatial equilibrium problem may be written to or read from this file. When the program begins execution, it asks for an initial IDF name. If you have an existing input data file, you may give the program the file name (and if necessary the drive specifier). In the case of an old file, the program will ask if you wish to have the file read into memory. In the usual case this is what you will want the program to do. If you do not want the existing data file read into memory, the program will ask you for an alternative file name. If you refuse to give one, the program will prompt to assure that you really want to destroy an existing data file. (The existing file is destroyed because the program must open it as a new file to write data to the file in case you wish to save the problem data). In the case of a new input data file, the program opens the file. However, no data are written to it until IDF is reset using the SET IDF command-function string or until program execution is terminated with the END command.

Once an input data file is read into memory, you may rerun the problem or make modifications, and then solve the modified problem. Whenever the SET IDF command-function sequence is invoked, the program checks to see if the current input data file is an old data file. If the file is an old file, the program gives you an opportunity to save the file. If you have made modifications, the program also gives you a chance to write the modified data file to the disk using a different file name. If you have not read an input data file into memory, as would be the case if you were entering data for a new problem, the program gives you an opportunity to save the problem data on the disk. The user can change the current input data file at any time by using the SET IDF command-function string. This command-function sequence allows modified versions of old data files to be saved on disk and also allows different problem data files to be read into computer memory. The file handling procedures discussed in this paragraph apply to the initial IDF prompt at the beginning of program execution, to any use of the SET IDF command-function string, and to program termination invoked via the END command.

The output data file (ODF) is treated in similar manner. In this case, the initial file should be a new data file, since the program does not read this file and cannot skip to the end of information on an old output data file. If the file already exists, the user is asked whether or not it should be destroyed. If the ODF file does not exist, a new file is opened and data may be written to it using the RPT command. The RPT command may be used several times within a single execution of the program to write reports for several spatial equilibrium problems on one output data file, or the SET ODF command-function string may be used to save the current output file and specify a different file name for subsequent reports.

**NOTE:** The program does not allow DOS 2.0 paths in file names. If you wish you could use the DOS CD (Change Directory) command to specify a path before executing my program. The procedure would be something like this. Suppose you have a hard disk drive called C: and you keep your spatial equilibrium problem data files in a directory named C:\SPATIAL\PROBLEMS. To use an input data file in this directory you could enter CD C:\SPATIAL\PROBLEMS at the DOS prompt before you begin execution of my program and answer the initial input data file prompt with C:File-Name. I prefer to copy the data

files to the current drive (or subdirectory on a hard disk) and work with a copy of the file rather than the original. I think that working with copies of files is a judicious precaution.

Functions NXS and NMS are used to define the number of regions. For exporters, the maximum is 10, and for importers the maximum is 25. The program enforces these limits. If you need to solve a larger problem the computer program must be modified, recompiled, and relinked. Note that you will need more memory and a lot more patience if you try to solve large problems with this program.

LXS and LMS are the respective exporter and importer region names. The names are restricted to 20 characters, and if you enter a longer name it will be truncated to 20 characters. Region names may contain any printable ASCII character.

The QLX and QLM functions are used to specify export and import quantity lower bounds. Exporters and importers may be forced to export (import) a specified minimum quantity. These constraints may be imposed by the user, but their primary use is internal to program GTP. The computer program totals the lower bound flow constraints (see TFL below) and sets the QLX and QLM vectors to the larger of the constraint totals or the actual minimum quantities. This is necessary, because in some conditions the sum of lower bound constraints may act as an export or import quantity lower bound. After the solution algorithm is invoked, the program resets the QLX and QLM vectors to their original (your input) values.

Functions QUX and QUM are the familiar market quota constraints. The  $i^{\text{th}}$  exporter may export no more than  $QUX_i$ , and the  $j^{\text{th}}$  importer may import no more than  $QUM_j$ . In the case where quota constraint is binding, an exporter (importer) will export (import) at the appropriate trade price as defined through the price linkage function, but the internal market price will be lower (higher) than the trade price.

VTX and VTM are respectively exporter and importer ad valorem tariffs. The ad valorem tariffs must be entered to the program as decimals; for example, 0.1 for 10 percent. The program will allow large (greater than 1.0 or 100 percent) and negative ad valorem tariffs but will prompt for confirmation of such values before it allows the solution algorithm to begin.

Functions STX and STM specify per unit or specific tariffs for exporting and importing regions. The specific tariffs are per unit charges levied on all exports or imports and must be input to the computer program in domestic currency units. As with ad valorem tariffs, the program allows large and negative specific tariffs but will ask for verification before starting the solution procedure.

The exchange rate functions are named ERX and ERM. The exchange rates are defined as units of base currency per unit of domestic currency. For example, if \$1US were equivalent to 200 Japanese yen, and the U.S. dollar were the base currency, then Japan's exchange rate would be 0.005 (1/200).

Trade flow lower and upper bounds are entered with the TFL and TFU functions.  $TFL_{ij}$  specifies a minimum trade flow between the  $i^{\text{th}}$  exporter and the  $j^{\text{th}}$  importer, and TFU is used to declare maximum trade flows between trade partners. For example, these constraints would be used to simulate the limits

in the 1983 bilateral trade agreement between the United States and the Soviet Union. If you enter trade flow constraints which are inconsistent with the quota constraints, the program "beeps" at you and refuses to try to solve the problem.

Function CTS is used to set per unit transport costs where  $CTS_{ij}$  is the cost in base currency of transporting a commodity unit from the  $i^{th}$  exporter to the  $j^{th}$  importer. Zero or negative transportation costs are permitted, but the program considers such transport costs to be potential errors and prompts for confirmation before invoking the solution algorithm.

TLE is used to set a 50 character run title. The title is used only on the hardcopy reports generated via the RPT command. The title function is included in the program as an aid designed to keep track of alternative solutions. I suggest that the TLE function be used before each call to the hardcopy report writers available through the RPT command. If you enter a title with more than 50 characters, the program will truncate the title. A title may contain any printable ASCII character.

The excess supply and demand schedules are declared with functions QSX and QDM. Function QSX may be used to see the current coefficient values or set new values for exporter excess supply schedules, and the analogous function for importers is QDM. Recall from the section on the mathematical model that the functional form is:

$$\text{Quantity} = \text{Alpha} + \text{Beta} * (\text{Price})^\text{Gamma}$$

which allows scalar, linear, constant elasticity, and mixed schedules. In the computer program coefficient Alpha is labeled "A", Beta is "B", and Gamma is "C."

Function PGX is used to set initial ("guess") estimates of the exporter (source) prices. The algorithm uses the exporter prices to derive importer prices so initial values for importer prices are not required. The solution procedure is not highly sensitive to initial price values, but the initial values should be within the magnitude of the solution prices. In fact, if the "optimal" prices are given to the algorithm as initial price values, the algorithm will not realize that the initial values are "optimal." So, don't worry about precise initial exporter price estimates.

Function RPC is used to set a relative price convergence criterion for the solution algorithm. The solution procedure also employs a relative quantity convergence criterion, but it is not controllable by the program user and is set internally to 0. Convergence test values are calculated across major iterations (subdivisions) of the solution algorithm. When either convergence criterion, price or quantity, is achieved the solution procedure terminates. The convergence criteria are applied to the worst case situation. The price convergence criterion is applied to the largest relative change in exporter or importer prices, and the quantity convergence criterion applies to the largest relative change across all export and import quantities. The convergence criteria are expressed in decimal form where the number of zeros is approximately the worst case number of digits of accuracy in the solution.

For example, 0.000001 corresponds to a minimum of five digits of accuracy. The default value of RPC is zero. The algorithm will proceed until either RPC or the internal relative quantity convergence value (0) is less than or equal

to approximately  $1.5 \times 10^{-8}$ . This corresponds to more than seven digits of accuracy for the worst case relative price or quantity change between major iterations.

The remaining functions, PTX, PTM, QTX, QTM, TFX, AND TFM, write reports to the screen. These reports are different than those produced by the report command RPT. If you like, you can route them to the printer with the PrtSc command. These reports give a short synopsis of the solution and are intended to provide a quick output. The reports generated by RPT are more comprehensive and provide more adequate data for comparing alternative solutions. PTX and PTM generate reports of trade, border, and domestic prices, and quota tariff equivalents. I define a trade price as the price at which a commodity is traded, a border price as the trade price less any tariffs for exporters or plus any tariffs for importers, and a domestic price as the internal price of the commodity. In the presence of binding quotas, the border price and the domestic price will not be the same. Functions QTX and QTM provide on screen trade quantity and revenue or cost reports, and functions TFX and TFM produce trade flow quantity and status reports.

### Command and Function Syntax

Program commands are entered at the prompt. Commands RUN, RPT, and END require no additional information. Commands SEE and SET require a function name and, perhaps, function information. If additional information is entered for RUN, RPT, or END, it is ignored since these commands prompt for further information, if necessary. The SEE and SET commands must be accompanied by a function; for example, use SET NXS to set the number of exporting regions.

Some functions may pertain to a large quantity of data. For example, there are 96 transportation costs (function CTS) in the example problem presented in this report. The user may wish to SEE or SET only a few of these values. To do this, the user may provide optional indexing information. The syntax of the 24 SEE/SET functions is respectively for scalar, vector, and array functions:

CMD FTN

CMD FTN [,][first-index] [,last-index]

CMD FTN [,][first-index] [,last-index] [,first-index] [,last-index]

Where: CMD represents SEE or SET,

FTN represents one of the first 24 program functions (IDF through RPC), and

[ ] represents an optional integer index.

If the optional indices are not included, the program assumes that you wish to work with the entire vector or array. If only one indice is given for an index pair (first-index, last-index) then the program assumes that the item indexed is the only item with which you wish to work. If you indicate an index range, then the program assumes that you wish to work with the inclusive elements. The command syntax for the screen report writers (PTX through TFM) is the same as that of the scalar functions. The command syntax may be clarified with some examples:

- |                 |                     |
|-----------------|---------------------|
| (a) SEE LXS     | (e) SEE CTS         |
| (b) SEE LXS 1   | (f) SEE CTS 1       |
| (c) SEE LXS 1,5 | (g) SEE CTS 2,4,3,6 |
| (d) SEE LXS 3,5 | (h) SEE CTS,,,5,6   |

Examples (a) through (d) illustrate the use of indices with vector functions. Example (a) defaults to all possible values of the exporter subscript, 1 through NXS. Example (b) requests the information for the first exporter only. Examples (c) and (d) indicate that the information be provided for a range of exporters; (c) for the first five exporters, and (d) for the third, fourth, and fifth exporters.

Examples (e) through (h) apply to array functions. Example (e) is similar to (a) in that all requested elements of the function are requested. In the case of arrays, the exporter indices are processed before the importer indices. Example (e) would display the transportation costs from the first exporter to each importer, then from the second exporter to each importer, and so forth. Example (f) would display the transportation costs from the first exporter to all importers. With example (g), the display would be restricted to the second, third, and fourth exporters and the third through sixth importers. The final example (h) illustrates the syntax used to display the transportation costs for all exporters and a selected range of importers. Either blanks or commas may be used as delimiters. Multiple blanks are ignored by the program, but the program assumes default values in the case of multiple commas (as in example (h) above).

### Data Entry

Data entry is performed using the SET command. SET FTN (where FTN is one of the first 24 functions, IDF through RPC) displays the current value of a function or function element(s) and allows the user to enter a new value. The file handling functions IDF and ODF are exceptions to the general case since they prompt for additional user input. The scalar functions (NXS, NMS, RPC, and TLE) display the current data on one line and prompt for new data on the next line. All other functions display data and prompt for new data on the same line. The data entry prompt is best explained by example:

> SET VTX

ID	Region Name	Old VTX	New VTX !
01	United States	.000	-

In this example, SET VTX was entered at the program prompt, and the program responded by showing the current ad valorem tariff for the first region which is named "United States." The underscore represents the curser position. At this point the user may enter a new value for the tariff followed by a <return> or enter only a <return>. If a new value is entered, it is restricted to 10 digits (a decimal point is counted as a digit). The default value of 0 is retained if the user enters only a <return>. All vector and array data entry prompts contain the exclamation point (!) to indicate the end of the input data field. In all cases the current value is retained as the default value.

### Convergence Progress

At the end of each major iteration of the solution algorithm, a cryptic message is written to the screen. The message contains the subdivision or major iteration count (subdivision), the current relative convergence test value for price convergence (RPC), the corresponding value for quantity convergence (RQC), the number of function evaluations for the excess supply schedules (CX) and excess demand schedules (CM), and the number of artificial labelings or "free pivots" (AL). An example of the convergence progress report is reproduced as table 4. This information may be used to follow the convergence progress and to indicate that the program is in fact running (see the comments pertaining to the 8087 coprocessor and execution time in the last section of the report).

When the solution algorithm terminates, it writes a message concerning the solution status. There are six possible messages:

- (1). Requested Convergence Attained (RPC),
- (2). Requested Convergence Attained (RQC),
- (3). Requested Convergence Attained (RPC and RQC),
- (4). Requested Convergence Could Not Be Attained,
- (5). Excessive Basis Change Column Ties, and
- (6). Basis Change Column Tie-Breaking Rule Failed.

The first three messages are self-explanatory. The fourth message is the normal termination message for the case where  $RPC = RQC = 0$ , since the algorithm will terminate automatically at a relative convergence of about  $1.5 \times 10^{-8}$ . The final two messages, (5) and (6), indicate abnormal termination. Message (5) indicates that your problem is highly degenerate. The most likely cause for this message is that the transportation rates are zero or that several exporters are able to supply several importers at the least cost price (the price linkage function tends to "breakdown" with zero transportation costs or with models that contain many nonprice responsive

Table 4--An Example of Convergence Progress

---

Starting VSM Algorithm						
Subdivision: 1	RPC = 1.13947167	RQC = .37767758	CX = 22	CM = 22	AL = 4	
Subdivision: 2	RPC = .35599548	RQC = .35177936	CX = 72	CM = 72	AL = 30	
Subdivision: 3	RPC = .02421318	RQC = .02684104	CX = 84	CM = 84	AL = 35

Subdivision: 13	RPC = .00000003	RQC = .00000002	CX = 359	CM = 359	AL = 265	
Subdivision: 14	RPC = .00000001	RQC = .00000001	CX = 386	CM = 386	AL = 286	
Exit VSM:	RPC = .00000001	RQC = .00000001	CX = 387	CM = 387	AL = 286	
Requested Convergence Could Not Be Attained						

---

regions). The sixth convergence message should never appear. If it does, the user should check the excess schedules very closely for feasibility. Note that this algorithm will not solve the standard transportation problem. There is no "super source" or "super sink." At least some exporters and importers must be price responsive.

### Scaling

The computer program tries to avoid numerical difficulties arising from poor scaling, but the user still needs to be aware that poor scaling may lead to ill-conditioned problems and bizarre error messages or nonsensical solution values. When choosing units, try to keep the product of price times quantity within a reasonable range, say below  $10^7$ . Also, if at all possible, the price-quantity products should be of similar magnitude for all regions in the model. For agricultural commodities, I have found that prices expressed in \$US per ton and quantity expressed in million metric tons or thousand metric tons are reasonable choices. I do not recommend building a corn model with prices expressed in cents per ton and quantity expressed in kilograms.

### COMPUTER HARDWARE REQUIREMENTS

The computer program is relatively large in terms of both memory and computational requirements. For the best IBM personal computer performance, at least 192K of RAM and an 8087 mathematical coprocessor are required. The program will run without an 8087 coprocessor, but you will need a 256K machine and your patience may wear rather thin while you wait for the solution algorithm to converge.

The program is written in Fortran 77 (the solution algorithm and the hardcopy report writers were downloaded from a large mainframe), and I used Microsoft Fortran Version 3.2 to compile and link it. The Microsoft compiler package contains some alternative floating point mathematical libraries to be used in different computing environments. One of the mathematical libraries is specifically designed for the 8087 coprocessor.

To illustrate the importance of the 8087 coprocessor, I ran the same problem with versions of the program linked with alternative mathematical libraries. The program size and solution times for the alternative libraries are shown in table 5. This problem has 6 exporting regions, 16 importing regions, and 15 binding trade flow constraints. Two of the exporting regions have scalar excess supply schedules, and the other four have constant elasticity schedules. The excess demand schedules are evenly split between scalar and constant elasticity form, eight of each. For each of the three runs, I used

Table 5--Sample Problem Solution Times Using Alternative Mathematical Libraries

<u>Library</u>	<u>Code Size (Bytes)</u>	<u>Time (Minutes:Seconds)</u>
8087.LIB	156916	4:00
ALTMATH.LIB	168764	15:30
MATH.LIB	166084	32:45

the same initial guesses for the exporter prices and set  $RPC = 0$ . The solution accuracy for each run was about eight digits.

The 8087 mathematical library may be used only if the computer has an 8087 coprocessor. The other two libraries (MATH and ALTMATH) may be used whether or not the machine has an 8087 coprocessor. Programs linked with the ALTMATH library do faster floating point operations than programs linked with the MATH library on machines that do not have an 8087 coprocessor. However, programs linked with ALTMATH will not use an 8087 coprocessor even if it is available. Programs linked with the MATH library will use an 8087 coprocessor if one is available. However, programs linked with MATH execute very slowly on machines that do not have an 8087 coprocessor.

I have not had an opportunity to test the program on an 8086 based machine. An 8086 based machine without an 8087 coprocessor should give somewhat better solution times than an IBM personal computer without an 8087 coprocessor.

### EXAMPLE PROBLEM

This section illustrates the step-by-step procedure to build and solve an actual spatial equilibrium model. I have chosen to use a 6 exporter and 16 importer model of world wheat trade for the example. This is the same model which was used as an example in comparing solution time in the preceding section. The model is similar to the model described in Holland and Sharples [2]. The only difference between the example model and the Holland-Sharples model is that the example model uses simple excess supply schedules while the Holland-Sharples model uses composite excess schedules with separate production, consumption, and stocks schedules.

The model in [2] was solved with a mainframe version of the GTP program which allows much more flexibility in excess schedule functional forms than the microcomputer version. The microcomputer version could be "tricked" into solving the model in [2] by specifying additional import regions which would correspond to the domestic use and stocks schedules of the composite excess schedules used in Holland-Sharples.

The assumptions embedded in the model and the data sources used for base period prices, quantities, and transportation costs may be found in the aforementioned reference. For the example, I assume that the user has formulated a model, has all necessary input data at hand, and is ready to solve the model with the computer.

### Notation

In the following pages, material that the computer program generated on the screen is printed "boldface," and data the user entered is printed "normal." A carriage return (or enter) is denoted with the symbol <return>. The program prompt is printed as >. The program prompt is actually a solid right arrow, one of the nonprintable ASCII characters.

### Getting Started

For day-to-day use, I renamed the 8087 version of the program GTP.EXE, and I usually operate from a RAM disk named B:. To run the program, I copy GTP.EXE

and the input data files I need from the hard disk to the RAM disk and enter GTP <return> at the B> prompt.

B> GTP <return>

This procedure will vary slightly if you have a different hardware configuration. In any case, program execution is initiated by typing the program name and a <return>.

The program responds by writing the following header, then prompts for initial names for the input data and output data files (IDF and ODF).

\*\*\*\*\*

Solution of the Generalized Transportation  
Problem Using the Vector Sandwich Method  
Fixed-Point Algorithm of Kuhn and MacKinnon.

Coded on an IBM-XT using Microsoft Fortran

Version 1.0 - October 1984

\*\*\*\*\*

Initial Input Data File Name (IDF)? WWM80S.IDF <return>

Initial Output Data File Name (ODF)? WWM80S.ODF <return>

In this example, we are entering data for a new problem. Therefore, I answered the IDF file name prompt with a name (WWM80S.IDF) which was not the same as an existing file on the logged drive. I could have included a drive designator in the file name. If a drive designator is not present in the file name, the program assumes that you wish to use the logged drive. I also entered a file name (WWM80S.ODF) for the initial output data file. Entering a <return> without file names at these file name prompts tells the program to use the default file names SCRATCH.IDF and SCRATCH.ODF.

Title and Number of Regions

The problem title is used only on the reports written via the RPT command. In general, one should enter a unique title if hardcopy reports of alternative versions of the problem are to be generated. I find that alternative titles are very helpful in keeping track of solutions. The title may contain any printable ASCII character and the default title is a null string.

> SET TLE <return>

50!

Old TLE:

New TLE: Holland-Sharples 1980 Base Short-Run Wheat Model <return>

The "50!" indicates the end of the 50-column field that the program allocates for the run title. The exclamation point is in column 50.

The sample problem has 6 exporting regions and 16 importing regions. This data should be entered before any region specific data, since the program uses the number of exporters and importers as default index ranges for all input and output vectors and arrays. Other problem data may be entered in any order. As can be seen in the output reproduced below, the default values are 10 exporting regions and 25 importing regions.

> SET NXS <return>

Old NXS: 10

New NXS: 6 <return>

> SET NMS <return>

Old NMS: 25

New NMS: 16 <return>

### Region Labels

The program allows 20-column labels for all exporting and importing regions in the model. The region labels are used by the SEE and SET functions, in the reports the program writes to the screen, and in the hardcopy reports generated with the RPT command. I suggest that region labels be entered immediately after the number of exporters and importers are entered, since the program uses the labels with the SEE and SET functions. The region labels may contain any printable ASCII character. The exclamation point in column 20 indicates the end of the region label field.

> SET LXS <return>

ID	Old LXS	New LXS	!
01	NO NAME REGION LABEL	Canada <return>	
02	NO NAME REGION LABEL	United States <return>	
03	NO NAME REGION LABEL	Argentina <return>	
04	NO NAME REGION LABEL	EEC-10 Export <return>	
05	NO NAME REGION LABEL	O. W. Europe Export <return>	
06	NO NAME REGION LABEL	Australia <return>	

> SET LMS <return>

ID	Old LMS	New LMS	!
01	NO NAME REGION LABEL	Central America <return>	
02	NO NAME REGION LABEL	Brazil <return>	
03	NO NAME REGION LABEL	Other S. America <return>	
04	NO NAME REGION LABEL	EEC-10 Import <return>	

05	NO NAME REGION LABEL	O. W. Europe Import <return>
06	NO NAME REGION LABEL	O. W. Europe Import <return>
06	NO NAME REGION LABEL	Eastern Europe <return>
07	NO NAME REGION LABEL	Soviet Union <return>
08	NO NAME REGION LABEL	People Rep. China <return>
09	NO NAME REGION LABEL	Japan <return>
10	NO NAME REGION LABEL	East Asia <return>
11	NO NAME REGION LABEL	Southeast Asia <return>
12	NO NAME REGION LABEL	South Asia <return>
13	NO NAME REGION LABEL	West Asia <return>
14	NO NAME REGION LABEL	North Africa <return>
15	NO NAME REGION LABEL	Central Africa <return>
16	NO NAME REGION LABEL	South Africa <return>

### Transportation Costs

Entering transportation costs is a straightforward though tedious process, since a per unit cost must be entered for each possible trade flow. The default value for transportation costs is zero. A 10-column data field is allowed for transportation costs and all other floating point data. The exclamation point is in the tenth column.

> SET CTS 1 <return>

### Trade Flow Constraints

Entering trade flow constraints is nearly as boring as entering transportation costs. The example problem does not have any upper bound trade flow constraints, and we use the program default value of 500,000 for all trade flow upper bounds. Also, the fifth exporting region in the example (O. W. Europe Export) does not have any lower bound trade flow constraints and we allow the program to insert the default value of zero for these constraint values.

### Excess Schedules

Entering excess schedule data is also a straightforward procedure. Users need to keep in mind that excess schedules must be specified in fixed functional form. The functional form is flexible enough for most applications, since it allows scalar, linear, and constant elasticity schedules. Note that the excess schedules must be written in the quantity dependent form, and the default schedule is scalar with a quantity value of zero. Also, recall that "A" corresponds to Alpha, "B" to Beta, and "C" to Gamma.

#### SET Functions

At this point in the data entry process, I decided that I needed to see all of the SET functions to insure that I had entered all of the data necessary for this spatial equilibrium problem. One way to get a list of the functions is illustrated below.

> SET <return>

Unrecognizable SET Function

<u>FTN</u>	<u>Definition</u>	<u>FTN</u>	<u>Definition</u>
IDF	Input Data File Name	ODF	Output Data File Name
NXS	Number of Exporters	NMS	Number of Importers
LXS	Exporter Names	LMS	Importer Names
QLX	Exporter Supply Lower Bounds	QLM	Importer Demand Lower Bounds
QUX	Exporter Supply Upper Bounds	QUM	Importer Demand Upper Bounds
VTX	Exporter Ad Valorem Tariffs	VTM	Importer Ad Valorem Tariffs
STX	Exporter Specific Tariffs	STM	Importer Specific Tariffs
ERX	Exporter Exchange Rates	ERM	Importer Exchange Rates
TFL	Trade Flow Lower Bounds	TFU	Trade Flow Upper Bounds
CTS	Cost of Transport Services	TLE	Run Title
QSX	Exporter Supply Schedules	QDM	Importer Demand Schedules
PGX	Exporter Initial Prices	RPC	Relative Price Convergence

In looking over the list, I discovered that I had forgotten to enter initial prices for the exporting regions.

### Initial Exporter Prices

Initial estimates of the prices for the exporting regions must be entered, since the program will not attempt to solve a spatial equilibrium problem, unless you give it some indication of the expected price levels. The program uses default values of -1 to insure that positive initial price guesses have been entered. I knew that actual wheat export prices for the base period in the example problem had been around \$200 per ton, so I used this value as an initial guess for all exporting regions (all prices are expressed in U.S. dollars and all exchange rates are one in this problem).

> SET PGX <return>

ID	Region Name	Old PGX	New PGX !
01	Canada	-1.000	200 <return>
02	United States	-1.000	200 <return>
03	Argentina	-1.000	200 <return>
04	EEC-10 Export	-1.000	200 <return>
05	O. W. Europe Export	-1.000	200 <return>
06	Australia	-1.000	200 <return>

### Price Convergence

The user may set the relative price convergence criteria or use the program default value of zero. Recall that if the convergence criteria is zero then the program will run the solution algorithm until the worst case relative price or quantity change is about  $1.5 * 10^{-8}$ . I recommend that you use the default value unless you are certain that a looser tolerance is appropriate for your problem. To see the relative price convergence value:

> SEE RPC <return>

Current RPC: .00000000

### Reviewing Input Data

The SEE command may be used at any time to review the data that you have entered or to see the program default values. In the examples below, I review the excess supply schedules and look at the default values that the program inserted for the exporter exchange rates, specific tariffs, and ad valorem tariffs. Since the program always uses the same default values for exporting and importing regions, I did not review the exchange rate and tariff data for the importing regions.

### Solving

The RUN command is invoked to solve a spatial equilibrium problem. The program first examines the input data for errors and potential errors. Errors are things like excess schedules with the wrong slope, inconsistent market quotas and trade flow constraints, and negative initial exporter prices. Potential errors are things like zero transportation costs and large or negative tariffs.

If errors are found, the program writes a message about them to the screen and refuses to try to solve the problem. If the program finds potential errors, it writes a message to the screen and asks whether or not to begin the solution algorithm. No errors or potential errors were found in the example problem.

### Screen Reports

The program can write six different reports to the screen. There are three report types: price and quota tariff equivalents; trade quantity, value, and revenue; and trade flow quantity and price linkage reports. Each of these reports is available for both exporters and importers.

The price and quota tariff equivalents report shows trade, border, and domestic prices by region. If binding quotas are present this report also displays the specific and ad valorem tariff equivalents.

The final set of screen reports shows the individual trade flows between regions, the value of the price linkage function, and the "state" of the trade flow. The price linkage function value may be interpreted as a shadow price. It is zero for "optimal" flows, negative for flows which are at the upper bound constraint, and positive for flows which are at the lower bound constraint. The "state" of the trade flow is OPT for an optimal (least cost) flow, LBC for a lower bound constrained flow, UBC for an upper bound constrained flow, and null for a nonoptimal, nonbinding flow.

#### Hardcopy Reports

When the RPT command is entered, a list of reports is presented to the user one by one. The reports are written to the output data file, if the user answers

the yes/no question with a Y (or y) or enters <return>. The hardcopy reports are printed after exiting program GTP with the DOS PRINT command or the COPY command. The hardcopy reports for this example problem are included as an appendix to this report.

> RPT <return>

#### Report Description

#### Exiting

Program execution is terminated with END command. The program asks some questions about your input data file (two input data files if you have read an input data file into the program and made modifications), and the output data file if the RPT command was used. Then the program returns to the operating system.

> END <return>

#### Printing Hardcopy Reports

In the example, the reports available with the RPT command were written to a file (WWM80S.ODF) on the logged drive. Now assume that you want to print these reports. As previously mentioned, the reports are written in a 133-column format, so you will need either a wide carriage printer or to set your 80-column printer to condensed print mode. Once the printer is set up, you need to enter one of the following standard DOS commands to print the file.

> PRINT WWM80S.ODF      or      > COPY WWM80S.ODF LPT1

After entering the print command, you'll have time to go get a cup of coffee and celebrate your achievement while the file is printing. The hardcopy reports for this example problem are reproduced in the Appendix.

#### Using an Existing Input Data File

Now suppose that you have an existing input data file and you want to make some modifications and resolve the problem. Consider the spatial equilibrium

problem I used for an example. What does this example problem imply about the elasticity of excess demand for wheat faced by the United States? In the example, the United States exported almost 43 million metric tons of wheat at a price of about \$175 per ton. We can fix United States exports at 42 and 44 million metric tons, solve the two spatial equilibrium problems, and then calculate an implied arc elasticity from the two price-quantity solutions. From the data reproduced below, I calculated an elasticity estimate of -0.7.
